Supporting Information

ABSTRACT: We investigate light–matter coupling in metallic crystals where plasmons coexist with phonons exhibiting large oscillator strength. We demonstrate theoretically that this coexistence can lead to strong light–matter interactions without external resonators. When the frequencies of plasmons and phonons are comparable, hybridization of these collective matter modes occurs in the crystal. We show that the coupling of these modes to photonic degrees of freedom gives rise to intrinsic surface plasmon–phonon polaritons, which offer the unique possibility to control the phonon properties by tuning the electron density and the crystal thickness. In particular, dressed phonons with reduced frequency and large wave vectors arise in the case of quasi-2D crystals, which could lead to large enhancements of the electron–phonon scattering in the vibrational ultrastrong coupling regime. This suggests that photons can play a key role in determining the quantum properties of certain materials. A nonperturbative self-consistent Hamiltonian method is presented that is valid for arbitrarily large coupling strengths.

KEYWORDS: plasmonics, polaritons, ultrastrong coupling, electron–phonon coupling, 2D materials, superconductivity

Using light to shape the properties of quantum materials is a long-standing goal in physics, which is still attracting much attention.1–3 Since the 1960s, it is known that superconductivity can be stimulated via an amplification of the gap induced by an external electromagnetic radiation.4–7 Ultrafast pump–probe techniques have been recently used to control the phases of materials such as magnetoresistive manganites,8 layered high-temperature superconductors,9 and alkali-doped fullerenes,2 by tuning to a specific mid-infrared molecular vibration. It is an interesting question whether the phases of quantum materials may also be passively modified by strong light–matter interactions in the steady state, without external radiation. Recently, the possibility of modifying superconductivity by coupling a vibrational mode to the vacuum field of a cavity-type structure has been suggested.9

This idea was then investigated theoretically in the case of an FeSe/SrTiO3 superconducting heterostructure embedded in a Fabry–Perot cavity.10 In this work, enhanced superconductivity is possible, on unrealistically large values of the phonon–photon coupling strength, in a regime where light and matter degrees of freedom totally decouple.11 This occurs beyond the ultrastrong coupling regime, which is defined when the light–matter coupling strength reaches a few tens of percents of the relevant transition frequency.12–14

Thanks to the confinement of light below the diffraction limit,15 an alternative approach to engineer strong16–20 and even ultrastrong light–matter coupling27–29 is the use of plasmonic resonators. The latter allow the propagation of tightly confined surface plasmon polaritons (SPPs), which are evanescent waves originating from the coupling between light and collective electronic modes in metals, called plasmons.28 Similarly, the collective coupling between light and vibrations of ions in solids gives rise to surface phonon polaritons. While suitable quantized theories to describe the ultrastrong coupling between SPPs or surface phonon polaritons and other quantum emitters such as excitons have been already reported,31,32 most quantized models used in the literature33,34 are not valid in this regime.

Strong coupling between SPPs in a 2D material and surface phonons of the substrate has stimulated considerable interest.35–40 While significant couplings cannot generally occur in the same crystal due to the screening of the ion charges by free electrons, exceptions have been recently reported considering surface phonons in InP or SiC nanocrystals coupled to photoexcited carriers.41 Other exceptions exist as a result of a transfer of oscillator strength from interband electronic transitions to the lattice. These include bilayer graphene,12 alkali fullerenes A6C60,43,44 organic conductors (e.g., K–TCNQ,45–47), and some transition metal compounds.48 Interestingly, some of these materials or similar

compounds feature superconductivity and charge density waves under certain conditions that are believed to be driven, at least partly, by electron–phonon scattering.\textsuperscript{49–53} Since the coexistence of collective electronic and ionic modes with large oscillator strength in the same crystal opens up the possibility to tune bulk phonon resonances,\textsuperscript{52,54} it is interesting to ask whether strong light–matter interactions between phonons, plasmons, and photons could occur in these materials in the absence of an external resonator, and if so, can this affect the electron–phonon scattering.

In this work, we propose and investigate the possibility to tune material properties of certain crystals via a hybridization of phonons, plasmons, and photons, which is intrinsic to the material, and without the use of an external resonator. The coexistence of plasmons and phonons within the same crystal gives rise to hybrid plasmon–phonon modes, which have been extensively studied in doped semiconductors and semimetals.\textsuperscript{55–59} Here, we show that while hybrid plasmon–phonon modes do not affect the electron–phonon scattering at the level of the random phase approximation, strong interactions between these modes and photons offer a unique possibility to control the energy and momentum of the resulting surface plasmon–phonon polaritons by tuning the electron density and the crystal thickness: “Dressed” phonons with reduced frequency arise in the ultrastrong coupling regime, where the electronic and ionic plasma frequencies become comparable to the phonon frequency. These dressed phonons are shown to exhibit unusually large momenta comparable to the Fermi wave vector in the case of quasi-2D crystals, which could lead to large enhancements of the electron–phonon scattering. Simply put, such enhancements are significant only for thin enough crystals, as they rely on the dressing of 3D phonon modes by 2D surface polaritons. These results suggest that photons can play a key role in determining the quantum properties of certain materials.

We utilize a self-consistent Hamiltonian method based on a generalization of that introduced in ref \textsuperscript{60}, which is valid for all regimes of interactions including the ultrastrong coupling regime, and in the absence of dissipation. This quantum description of surface plasmon–phonon polaritons provides an ideal framework to investigate how the latter can affect the quantum properties of the crystal. Furthermore, our method can be generalized to various surrounding media and geometries of interest such as layered metallo-dielectric metamaterials and simple nanostuctures and differs from the usual effective quantum description of strong coupling between excitons and quantized SPPs.\textsuperscript{24,33,34} We show in the Supporting Information that the latter model leads to unphysical behaviors in the ultrastrong coupling regime.

The paper is organized as follows: (i) We first introduce the total Hamiltonian of the system under consideration and (ii) diagonalize the matter part leading to plasmon–phonon hybridization in the crystal. (iii) We derive the coupling Hamiltonian of these hybrid modes to photonetic degrees of freedom, which gives rise to intrinsic surface plasmon–phonon polaritons. (iv) We determine the Hamiltonian parameter and its eigenvalues self-consistently using the Helmholtz equation and characterize the properties of the resulting surface plasmon–phonon polaritons. (v) We show that while plasmon–phonon hybridization cannot solely modify the electron–phonon scattering at the level of the random phase approximation (RPA), the coupling of these hybrid modes to photons could lead to large enhancements of the electron–phonon scattering in the crystal.

### QUANTUM HAMILTONIAN

We consider a metallic crystal of surface $S$ and thickness $l$ in air, which contains a free electron gas and a transverse optical phonon mode with frequency $\omega_{\text{po}}$. The excitation spectrum of the electron gas features a collective, long-wavelength plasmon mode with plasma frequency $\omega_{\text{pl}}$ as well as a continuum of individual excitations called electronic dark modes that are orthogonal to the plasmon mode. Both plasmons and phonons are polarized in the directions $u_2$ and $u_3$ (Figure 1). The Hamiltonian is derived in the Power–Zienau–Woolley representation,\textsuperscript{63} which ensures proper inclusion of all photon-mediated dipole–dipole interactions and can be decomposed as $H = H_{\text{mat}} + H_{\text{el–pt}}$ with $H_{\text{mat}} = H_{\text{pt}} + H_{\text{mat–pt}} + H_{\text{mat–pt}}$. The first term in $H_{\text{el–pt}}$ reads

$$H_{\text{pt}} = \frac{1}{2\epsilon_0} \int d\mathbf{R} \epsilon^2(R) + \frac{1}{2\epsilon_0} \int d\mathbf{R} \mathbf{H}^2(R)$$

and corresponds to the photon Hamiltonian. $c$ denotes the speed of light in vacuum, $R \equiv (r, z)$ the 3D position, $\epsilon_0$ is the vacuum permittivity, and $\mathbf{D}$ and $\mathbf{H}$ are the displacement and magnetic fields, respectively. The light–matter coupling term reads

$$H_{\text{mat–pt}} = -\frac{1}{\epsilon_0} \int d\mathbf{R} \mathbf{P}(R) \cdot \mathbf{D}(R).$$

Here, $\mathbf{P} = \mathbf{P}_{\text{pl}} + \mathbf{P}_{\text{ph}}$ denotes the matter polarization field associated with the dipole moment density, where $\mathbf{P}_{\text{pl}}$ and $\mathbf{P}_{\text{ph}}$ correspond respectively to the plasmon and phonon contributions. [Our method can be easily generalized when phonons are replaced by excitons, by considering the appropriate polarization field.] The matter Hamiltonian is decomposed as $H_{\text{mat}} = H_{\text{pt}} + H_{\text{pl}} + H_{\text{ph}}$, where $H_{\text{pt}}$ and $H_{\text{pl}}$ denote the contributions of free phonons and plasmons, which are provided in the Supporting Information, and $H_{\text{ph}} = \frac{1}{2\epsilon_0} \int d\mathbf{R} \mathbf{P}^2(R)$ contains terms $\propto \mathbf{P}_{\text{pl}} \cdot \mathbf{P}_{\text{ph}}$ and a direct plasmon–phonon interaction $\propto \mathbf{P}_{\text{pl}} \cdot \mathbf{P}_{\text{ph}}$. Finally, $H_{\text{el–pt}}$ includes the contribution of the free, individual electrons (electronic dark modes), as well as the coupling Hamiltonian between electronic dark modes and phonons.

### DIAGONALIZATION OF THE MATTER HAMILTONIAN

Hybrid plasmon–phonon modes have been extensively studied in doped semiconductors and semimetals.\textsuperscript{55–59} In this section,
we propose a derivation of these hybrid modes using a nonperturbative quantum method. In order to diagonalize $H_{\text{mat}}$, the phonon polarization $P_{\text{ph}}$ is written in terms of the bosonic phonon annihilation and creation operators $b_{Q\nu}$ and $\tilde{b}_{Q\nu}'$, with the 3D wave vector $Q \equiv (q, q, \nu)$ and $\alpha = \parallel, \perp$ the polarization index. The lattice polarization field $P_{\text{lat}}$ is proportional to the ion plasma frequency $\omega_p = \sqrt{\frac{\sum_{\text{ion}} Z_i N_i}{3\epsilon_{\text{ion}}}}$

which plays the role of the phonon–photon coupling strength.\textsuperscript{62} Here, $N_i$ denotes the number of vibrating ions with effective mass $M$ and charge $Ze$ in a unit cell of volume $a^3$. The plasmon polarization $P_{\text{pl}}$ is provided by the dipolar description of the free electron gas corresponding to that of the RPA.\textsuperscript{56} In the long-wavelength regime, $P_{\text{pl}}$ is written in terms of the bosonic plasmon operators $P_{\text{cky}}$ and $P_{\text{cky}}'$ ($K$ denotes the 3D electron wave vector), superpositions of electron–hole excitations with wave vector $Q$ across the Fermi surface. As explained in the Supporting Information, $H_{\text{mat}}$ can be put in the diagonal form $H_{\text{mat}} = \sum_{Q, \nu, \pm} \hbar \omega_Q \Pi_{Q\nu}^\pm \Pi_{Q\nu}^\mp$, where the hybrid plasmon–phonon operators $\Pi_{Q\nu}$ are superpositions of $b_{Q\nu}$ and their Hermitean conjugates, and satisfy the bosonic commutation relations $[\Pi_{Q\nu}, \Pi_{Q'\nu'}'] = \delta_{QQ'} \delta_{\nu\nu'} \delta_{\sigma\sigma'}$. The hybrid mode frequencies $\omega_j$ are represented in Figure 1 and are given by

$$2\omega_j^2 = \omega_0^2 + \omega_3^2 \pm \sqrt{\left(\omega_0^2 - \frac{\omega_3^2}{\omega_0^2} - \frac{\omega_p^2}{\omega_0^2 - \omega_3^2}\right)^2 + 4\omega_0^2\omega_3^2}$$

(1)

Here, $j = 1$ and $j = 2$ refer respectively to the signs $-\pm$, and the longitudinal phonon mode with frequency $\omega_0 = \sqrt{\omega_0^2 + \omega_3^2}$ is determined by the combination of the short-range restoring force related to the transverse phonon resonance, and the long-range Coulomb force associated with the ion plasma frequency. The diagonalization procedure of $H_{\text{mat}}$ further provides the well-known transverse dielectric function of the crystal:\textsuperscript{55}

$$\epsilon_{\text{tr}}(\omega) = 1 - \frac{\omega_0^2}{\omega^2} = -\frac{\omega_p^2}{\omega^2 - \omega_0^2}$$

(2)

One can then use the eigenmodes basis of the matter Hamiltonian to express the total polarization field as

$$P(R) = \sum_{Q, \alpha=\pm} \frac{\hbar \epsilon_{\text{cky}}^2}{2\omega_v V} \left(\Pi_{Q\alpha}^+ + \Pi_{Q\alpha}'\right) e^{-Q R} u_{\alpha_R}$$

(3)

with

$$g_i = \frac{\omega_i^2(1 + \omega_p^2/\omega_i^2)}{\omega_0^2 - \omega_i^2} - \frac{\omega_3^2}{\omega_0^2 - \omega_i^2} \sqrt{\frac{\omega_0^2}{\omega_i^2} + \frac{\omega_3^2\omega_i^2}{\omega_0^2 - \omega_i^2}}$$

and $V = Sl$. In the absence of phonon–phonon coupling ($\nu_{ph} = 0$), the two modes $j = 1, 2$ reduce to the bare phonon and plasmon. A similar situation occurs for $\nu_{ph} \neq 0$, in the case of large plasmon–phonon detunings. Both in the high $\omega_{pl} \gg \omega_0$ and low $\omega_{pl} \ll \omega_0$ electron density regimes, the hybrid modes reduce to the bare plasmon and phonon excitations, and the plasmon contribution prevails in the polarization field $P(R)$. As explained in the following, when the latter interacts with the photonic displacement field $D$, this simply results in the formation of SPPs coexisting with bare phonons. The latter are either transverse phonons with frequency $\omega_0$, or longitudinal phonons with frequency $\omega_0$, in the case $\omega_{pl} \ll \omega_0$ (Figure 1). In the following, we focus on the most interesting case occurring close to the resonance $\omega_{pl} \approx \omega_0$ where plasmon–phonon hybridization occurs.

### COUPLING TO PHOTONS

Due to the breaking of translational invariance in the $z$ direction, the 3D photon wave vector can be split into an in-plane and a transverse component in each media as $Q = q + if_{\sigma} \mathbf{u}_\sigma$, where $n = d, c$ refers to the dielectric medium and the crystal, respectively. For a given interface lying at the height $z_0$, the electromagnetic field associated with surface waves decays exponentially on both sides as $e^{\pm \gamma_{\parallel} (z - z_0)}$ with the (real) penetration depth $\gamma_{\parallel}$. The displacement and magnetic fields can be written as superpositions of the fields generated by each interfaces $m = 1, 2$, namely,

$$D(R) = \sum_{Q, m} \sqrt{\frac{4e_\gamma \hbar c}{S}} e^{iQ \nu_m(z)} D_m$$

and

$$H(R) = \sum_{Q, m} \frac{4e \gamma \hbar c}{S} e^{iQ \nu_m(z)} H_m$$

with $\gamma_m$ the frequency of the surface waves (still undetermined) and $Q \equiv \pm q \equiv \pm Q_f$. The mode profile functions $u_{\nu_m}(z)$ and $v_{\nu_m}(z)$ depending on $\nu_m$ are provided in the Supporting Information. Using these expressions, the photon Hamiltonian takes the form

$$H_{pe} = \hbar c \sum_{Q, m, m'} (A_{Qnm} D_m D_{-m'} + B_{Qnm} H_m H_{-m'})$$

where the overlap matrix elements $A_{Qnm}$ and $B_{Qnm}$ depend on the parameters $\gamma_m$ and $\gamma_f$. The next step corresponds to finding the electromagnetic field eigenmodes, which consist of a symmetric and an antisymmetric mode, such that the photon Hamiltonian can be put in the diagonal form:

$$H_{pe} = \hbar c \sum_{Q, \sigma=\pm} (\alpha_{Q\sigma} D_{Q\sigma} D_{-Q\sigma} + \beta_{Q\sigma} H_{Q\sigma} H_{-Q\sigma})$$

with

$$\alpha_{Q\sigma} = (A_{Q1} \pm A_{Q2})/\sqrt{2}, \quad \beta_{Q\sigma} = (B_{Q1} \pm B_{Q2})/\sqrt{2}, \quad D_{Q\sigma} = (D_{Q\sigma} \pm D_{Q\sigma})/\sqrt{2}, \quad H_{Q\sigma} = (H_{Q\sigma} \pm H_{Q\sigma'})/\sqrt{2}$$

and a similar expression for $H_{Q\sigma'}$. The new field operators $D_{Q\sigma}$ and $H_{Q\sigma}$ satisfy the commutation relations $[D_{Q\sigma}, H_{Q\sigma'}] = -i C_{Q\sigma} \delta_{Q\sigma\sigma'} \delta_{Q\sigma'}$, together with the properties $D_{Q\sigma} = D_{Q\sigma}^\dagger$, and $H_{Q\sigma} = H_{Q\sigma}^\dagger$. The constant $C_{Q\sigma}$ is determined using the Ampère’s circuital law, which provides

$$C_{Q\sigma} = \frac{\omega_0}{2\omega_{pl}}$$

The light–matter coupling Hamiltonian $H_{\text{mat} pe}$ is derived using the expression of $D(R)$ in the new basis together with eq 3. While $\omega_0$ is a good quantum number due to the in-plane translational invariance, the perpendicular wave vector of the 3D matter modes $q_m$ is not. In the light–matter coupling Hamiltonian $H_{\text{mat} pe}$ photon modes with a given $q$ interact with linear superpositions of the 3D matter modes exhibiting different $q_m$. The latter are denoted as quasi-2D “bright” modes and are defined as $\nu_{Qnm} = \sum_{Q, m, m'} \delta_{Qnm} \Pi_{Q\sigma m}$. The photon $\nu_{Qnm}$ stem from the overlap between the displacement and the polarization fields and is determined by imposing the commutation relations $[\nu_{Qnm}, \nu_{Q'n'm'}'] = \delta_{QnQ'n'} \delta_{\sigma\sigma'} \delta_{fj'}$. 

DIO: 10.1021/acsphotonics.9b00268

ACS Photonics XXXX, XXX, XXX--XXX
Using a unitary transformation, the matter Hamiltonian can be decomposed as $H_{\text{mat}} = \sum_{q,\sigma} \mathcal{H}_q^{\sigma} + H_{\text{dark}}$, where the second term is the contribution of the “dark” modes that are orthogonal to the bright ones and which do not interact with photons. Without this contribution, the polaron Hamiltonian reads $H^\sigma = \sum_{q,\sigma} \mathcal{H}_q^{\sigma} \mathcal{H}_q - \sum_i h\bar{\Omega}_q^{\sigma} (\pi_q^{\sigma} + \pi_q^{\sigma}) D_{qq}$

and the vacuum Rabi frequency

$$\Omega_q^{\sigma} = g_i \sqrt{\frac{c^2 q^2}{\tilde{\alpha}_q^2}} \times \sqrt{\frac{q^2 + \gamma_c^2 (1 - \epsilon^{-q^2} \omega_i)}{\gamma_c^2} + 2 s \epsilon^{-q^2} (q^2 - \gamma_c^2)}$$

**Surface Plasmon–Phonon Polaritons**

The Hamiltonian $H_{\text{pol}}$ exhibits three eigenvalues in each subspace ($q, \sigma$), and only the lowest two (referred to as lower and upper polaritons) correspond to surface modes (below the light cone). At this point, we have built a Hamiltonian theory providing a relation between the field penetration depths $\gamma_q$ and the surface wave frequencies $w_{\text{ph}}$, where $\zeta = \text{LP, UP}$ refers to the lower (LP) and upper (UP) polaritons. This eigenvalue equation can be combined with the Helmholtz equation $\epsilon_q \omega^2 / c^2 = q^2 - \gamma_q^2$ in order to determine these parameters.

We use a self-consistent algorithm which starts with a given frequency $w_{\text{ph,LP}}$, then determine $\gamma_q$ from the Helmholtz equation with $\epsilon_q = 1$ and $\epsilon_q (w_{\text{ph,LP}})$ given by eq 2 and use these $\gamma_q$ to compute the parameters entering the Hamiltonian $H_{\text{pol}}$. The latter is diagonalized numerically, which allows determining the new $w_{\text{ph,LP}}$. The algorithm is applied independently for the symmetric ($\sigma = +$) and antisymmetric ($\sigma = -$) modes until convergence, which is ensured by the discontinuity of both light and matter fields at each interface.

We now use this method to study the surface polaritons in our system. As an example, we consider the case $\omega_i = 1.5 \omega_0$ with different crystal thickness $q_0 l = 10$ (Figure 2a) and $q_0 l = 0.01$ (Figure 2b) and compute the surface polariton frequencies $w_{\text{ph}}$ (top panels), as well as their phonon ($i = \text{pn}$), plasmon ($i = \text{pl}$), and photon ($i = \text{ph}$) admixtures $W_{\text{ph}}^{\text{ph}}$ for $\nu_{\text{ph}} = 0$ and $\nu_{\text{ph}} = 0.5 \omega_0$ (bottom panels). Precise definitions of these quantities are provided in the Supporting Information, and $l$ and $q$ are both normalized to $q_0 = \omega_0 / c$. Considering typical mid-infrared phonons with $\hbar \omega_0 = 0.2$ eV, the two dimensionless parameters $q_0 l = 10$ and $q_0 l = 0.01$ correspond to $l = 10 \mu$m (first case) and $l \approx 0.2$ nm (second case), respectively.

In the first case (Figure 2a), the two surface modes at each interface have negligible overlap, and the modes $\sigma_q$ therefore coincide. For $\nu_{\text{ph}} = 0$, the plasmon–phonon coupling is responsible for the appearance of an SPP mode (black line) with frequency $w_0^\sigma$ which enters in resonance with the phonon
mode at \( q_0 \approx 2.2q_0 \). While for \( q \ll q_0 \) this SPP is mainly composed of light (\( \omega_0^2 \sim q^2 \)), it features a hybrid plasmon–phonon character for \( q \sim q_0 \) and becomes mostly plasmon-like as \( \omega_0^2 \) approaches the surface plasmon frequency \( \omega_{0s}^2 / \sqrt{2} \) for \( q \gg q_0 \). For \( \nu_{pn} \neq 0 \), a splitting between the two polaritons branches (thick red and blue lines) is clearly visible, and the latter consist of a mix between phonons, plasmons, and photons in the vicinity of \( q = q_0 \). In the regime \( q > q_0 \) since the mostly phonon-like LP exhibits a \( \sim 25\% \) plasmon admixture, this polariton mode can be seen as a “dressed” phonon with frequency red-shifted from \( \omega_0 \). Similarly, the “dressed” plasmon mode (UP) is blue-shifted from the surface mode frequency \( \omega_{0s}^2 / \sqrt{2} \) due its \( \sim 25\% \) plasmon weight.

The frequencies of the LP (red line) and UP (blue line) at resonance are represented as a function of \( \nu_{pn}/\omega_0 \) in the inset. Here, the resonance is defined by the condition \( \omega_0^2 \approx \omega_{0s} \), which provides \( \nu \approx 2.2q_0 \). We observe that the polariton splitting \( \omega_{0s}^\text{LP} - \omega_{0s}^\text{UP} \) is symmetric with respect to \( \omega_{0s}^\text{UP} = \omega_0 \) (black dotted line) for \( \nu_{pn} \ll \omega_0 \) and becomes slightly asymmetric in the ultrastrong coupling regime,\(^{12,12} \) when \( \nu_{pn} \) is a non-negligible fraction of \( \omega_0 \). Furthermore, the splitting is found to decrease rapidly as the electronic plasma frequency \( \omega_{el} \) is increased.

In the second case \( q_0 = 0.01 \) (Figure 2b), the crystal is thinner than the penetration depth \( \gamma_c \) of the surface waves at the two interfaces, and the latter overlap. This results in two sets of modes \( \sigma = \pm \) with different frequencies. For \( \nu_{pn} = 0 \), the symmetric and antisymmetric SPPs with frequency \( \omega_0^0 = \omega_0 \) are represented as black dashed and solid lines, respectively. The resonance between the symmetric SPP and the phonon mode occurs for \( q \approx q_0 \) in the regime where the symmetric SPP is mostly photon-like with \( \omega_0^0 \approx \omega_\text{ph} \). Interestingly, the resonance between the antisymmetric SPP and the phonon mode is now shifted to a large wave vector \( q \approx 220q_0 \) where the antisymmetric SPP exhibits a pure plasmonic character. For \( q/q_0 \to \infty \), the two SPPs \( \sigma = \pm \) converge to the surface plasmon frequency \( \omega_{0s}^2 / \sqrt{2} \). For \( \nu_{pn} \neq 0 \), the antisymmetric LP (thick red solid line) and UP (thick blue solid line) are split in the vicinity of the resonance \( q \approx 220q_0 \) while the symmetric polaritons (thick colored dashed lines) do not feature any anticrossing behavior for \( q \approx q_0 \). Similarly to that in (a), the LPs \( \sigma = \pm \) can be seen as dressed phonon modes with frequencies red-shifted from \( \omega_0 \) for large \( q \) due to their plasmon admixtures. Here, however, these dressed phonons can propagate with very large wave vectors comparable to the electronic Fermi wave vector.

### ELECTRON–PHONON SCATTERING

We now show that the ability to tune the energy and wave vector of the dressed phonons can affect the electron–phonon scattering in the crystal. The coupling Hamiltonian between individual electronic (dark electronic delocalized) and phonon modes reads\(^{62} \)

\[
H_{el-phon} = \sum_{K} \hbar \xi_{K} C_{K}^{\dagger} C_{K} + \sum_{K,\sigma} \hbar M_{\sigma} C_{K}^{\dagger} \Phi_{\sigma}^{*} (B_{\sigma} + B_{\sigma}^{\dagger})
\]

(4)

The Fermionic operators \( C_{K} \) and \( C_{K}^{\dagger} \) annihilate and create an electron with wave vector \( K \) and energy \( \hbar \xi_{K} \) (\( K \equiv |K| \)) relative to the Fermi energy. For simplicity, we assume a 3D spherical Fermi surface providing \( \xi_{K} = \hbar (K^{2} - K_{F}^{2})/(2m) \), with \( m \) the electron effective mass and \( K_{F} \) the Fermi wave vector, and that the coupling constant \( M \) does not depend on \( Q \) as shown theoretically for intramolecular phonons in certain crystals.\(^{63} \)

Electron–phonon interactions are usually characterized by the dimensionless coupling parameter \( \lambda \), which quantifies the electron mass renormalization due to the coupling to phonons.\(^{55} \) At zero temperature, \( \lambda \) is defined as

\[
\lambda = \frac{1}{N_{3D}} \sum_{K} \delta(\xi_{K}) \mathcal{R}(\omega_{K}(\omega)) \left| \partial_{\omega} \Sigma_{\omega} \right|_{\omega=0}
\]

where \( \mathcal{R} \) stands for real part, \( N_{3D} = \sum_{K} \delta(\xi_{K}) = \frac{V_{m} K_{F}}{2 \pi^{2} \hbar} \) is the 3D electron density of states at the Fermi level, and \( \partial_{\omega} \Sigma_{\omega}(\omega) \right|_{\omega=0} \) denotes the frequency derivative of the retarded electron self-energy \( \Sigma_{\omega}(\omega) \) evaluated at \( \omega = 0 \). An equation of motion analysis\(^{24} \) of the electron Green’s function (GF) \( G_{K}(\omega) = -i(\epsilon_{K}(\omega) - \omega_{K}(\omega)) \) allows to write the electron self-energy as

\[
\Sigma_{\omega}(\omega) = \sum_{Q,\sigma} i M_{\sigma}^{2} \int \frac{d\omega'}{2\pi} G_{K-Q}(\omega + \omega') B_{Q\sigma}(\omega')
\]

(5)

where \( B_{Q\sigma}(\omega) = -i \int d\tau e^{-i\omega \tau} \langle B_{K}(\tau) B_{Q\sigma}(0) \rangle \) is the phonon GF written in the frequency domain, and \( B_{K}(\tau) = B_{K}\uparrow \sigma + B_{K}\downarrow \sigma \).

In the absence of phonon–phonon coupling (\( \nu_{pn} = 0 \)), there is no hybridization between phonons and plasmons, or is there coupling to photons. Photons therefore enter the Hamiltonian \( H_{el} \) only in the free contribution \( H_{el} = \sum_{Q,\omega} \hbar \omega_{Q} B_{Q\sigma}^{\dagger} B_{Q\sigma} \).

In this case, the equation of motion analysis simply provides \( B_{Q\sigma}(\omega) = 2\omega_{Q}/(\omega^{2} - \omega_{Q}^{2}) \). Using this expression together with the noninteracting electron GF \( G_{K}^{0}(\omega) = 1/(\omega - \epsilon_{K}) \) in eq. 5, one can compute the electron–phonon coupling parameter for \( \nu_{pn} = 0 \) as

\[
\lambda_{0} = \frac{2|M|^{2}}{N_{3D} \omega_{0}} \sum_{K} \delta(\xi_{K}) \sum_{Q} \delta(\omega_{Q} - \omega_{0}) = \frac{2|M|^{2} N_{3D}}{\omega_{0}}
\]

In the presence of phonon–phonon coupling (\( \nu_{pn} \neq 0 \)), the phonon dynamics is governed by the Hamiltonian \( H_{el}^{0} \) which includes the coupling of phonons to plasmons and photons. It is therefore convenient to express the 3D phonon operators \( B_{Q} \) and \( B_{Q\sigma} \) in terms of the 3D hybrid modes \( \Pi_{Q\upsilon} \) and \( \Pi_{Q\sigma} \) and then project the latter onto the quasi-2D bright and dark modes such that the electron–phonon Hamiltonian eq 4 takes the form \( H_{el-Photon} = \sum_{Q,\sigma} \hbar \xi_{Q} C_{Q}^{\dagger} C_{Q} + H_{el-Photon}^{(B)} + H_{el-Photon}^{(D)} \). The contribution of the bright modes reads

\[
H_{el-phon}^{(B)} = \sum_{K,\sigma\sigma',j} \hbar M_{\sigma\sigma'}^{j} (Q) c_{K}^{\dagger} c_{K-Q}^{\dagger} (\pi_{Q\sigma} + (\pi_{Q\sigma}))
\]

while the contribution \( H_{el-phon}^{(D)} \) of the dark modes that do not interact with photons is given in the Supporting Information.

Here, \( \eta_{\sigma} = \chi_{j} \left( \frac{a_{\sigma}/a_{0}}{a_{\sigma}/a_{0}} \right) \) where \( \chi_{j} = \frac{\nu_{pn} M_{\sigma}^{1/2}}{a_{\sigma}/a_{0}} \) is associated with the hybrid mode weights of the phonons. The electron self-energy due to the interaction with bright modes reads

\[
\Sigma_{K}^{\text{B}}(\omega) = \sum_{Q,\sigma,\sigma',j} \iota \eta_{\sigma}^{2} |M_{\sigma\sigma'}^{j}(Q)|^{2} \int \frac{d\omega'}{2\pi} G_{K-Q}(\omega + \omega') B_{Q\sigma}(\omega')
\]

(6)
where \( B_{q\eta}(\omega) = -i\int d\tau \text{exp}(i\mathbf{q}\cdot\mathbf{r})\tau_{q\eta}(0) \) and \( \tau_{q\eta} = \tau_{q\eta}^{\text{ph}} + \pi_{q\eta}^{\text{ph}} \). As detailed in the Supporting Information, we now use the equation of motion theory to calculate the GF \( B_{q\eta}(\omega) \). For \( \nu_{\text{ph}} = 0 \), one simply obtains \( B_{q\eta}(\omega) = 2\bar{o}_{\eta}/(\omega^{2} - \bar{o}_{\eta}^{2}) \), which provides \( B_{q\eta}(\omega) = B_{q\eta}^{(0)}(\omega) \) since \( \bar{o}_{\eta} = \omega_{0} \) (and \( \bar{o}_{\eta} = \omega_{0} \)). In this case, \( \eta_{1} = 1, \eta_{2} = 0 \), and only the pure phonon term \( j = 1 \) therefore contributes to \( \Sigma_{k}^{(B)} \). We then calculate \( B_{q\eta}(\omega) \) and the self-energy eq 6 for \( \nu_{\text{ph}} \neq 0 \) and decompose the electron–phonon coupling parameter into its bright and dark mode contributions: \( \lambda = \lambda^{(B)} + \lambda^{(D)} \) for \( \nu_{\text{ph}} \neq 0 \), and \( \lambda_{0} = \lambda_{0}^{(B)} + \lambda_{0}^{(D)} \) for \( \nu_{\text{ph}} = 0 \). The contributions \( \lambda^{(B)} \) and \( \lambda^{(D)} \) are different because bright modes interact with photons for \( \nu_{\text{ph}} \neq 0 \), while they do not for \( \nu_{\text{ph}} = 0 \). Similarly, \( \lambda_{0}^{(B)} \) and \( \lambda_{0}^{(D)} \) are a priori different since dark modes are hybrid plasmon–phonon modes for \( \nu_{\text{ph}} \neq 0 \), while they reduce to bare phonons and plasmons for \( \nu_{\text{ph}} = 0 \). However, we show in the Supporting Information that \( \lambda_{0}^{(D)} = \lambda_{0}^{(B)} \) (Ref 52), which means that, at the level of the RPA, the hybridization between plasmons and phonons cannot solely lead to a modification of the electron–phonon scattering. Finally, the relative enhancement of the electron–phonon coupling parameter reads \(^{52}\)

\[
\frac{\Delta \lambda}{\lambda_{0}} = \frac{\lambda - \lambda_{0}}{\lambda_{0}} = \frac{1}{N^{2}_{3D}} \sum_{\mathbf{k}} \delta(\zeta_{k}) \sum_{\alpha,\sigma} (\varphi_{q\alpha}^{(0)} - 1) |J^{(0)}_{\text{ph}}(\mathbf{Q},\mathbf{r})|^{2} \delta(\zeta_{-\mathbf{q} -\mathbf{Q}} - \mathbf{r})
\]

where the function \( \varphi_{q\eta} \) is given in the Supporting Information. The latter describes the renormalization of the phonon energy due to the coupling to plasmons and phonons and depends on the polariton frequencies \( w_{p\alpha} \). It is represented in Figure 3a together with the frequency dispersion of the LPs \( w_{q\eta \perp \mathbf{p}} / \omega_{0} \) corresponding to the red solid and dashed lines in Figure 2b. First, we find that the contributions of the LPs to \( \varphi_{q\eta} \) largely dominate over the contributions of the other polaritons. Second, we observe that \( \varphi_{q\eta} \) is anticorrelated with the dispersion of the LPs, whenever the latter exhibit a finite phonon weight. For instance, \( \varphi_{q\eta} \) reaches large values in the region \( q \ll q_{0} \) where the frequency of the antisymmetric LP (\( \approx 35\% \) phonon for \( \nu_{\text{ph}} = 0.5\omega_{0} \)) is far away from the bare phonon frequency. In contrast, while \( w_{q\eta \perp \mathbf{p}} \ll \omega_{0} \) in this region, \( \varphi_{q\eta} \approx 1 \) since the symmetric LP is fully photon-like for \( q \ll q_{0} \). Note that for \( \nu_{\text{ph}} / \omega_{0} \rightarrow 0 \), the LPs for \( q > q_{r} \) are fully phonon-like with \( w_{q\eta \perp \mathbf{p}} \rightarrow \omega_{0} \) and one finds that \( \varphi_{q\eta} \rightarrow 1 \) does not contribute to \( \Delta \lambda / \lambda_{0} \) in this region. For \( q < q_{r} \), \( \varphi_{q\eta} \) does not contribute to \( \Delta \lambda / \lambda_{0} \) because of the vanishing phonon weight of the LP for \( \nu_{\text{ph}} / \omega_{0} \rightarrow 0 \).

The relative enhancement of the electron–phonon coupling \( \Delta \lambda / \lambda_{0} \) is represented in Figure 3b as a function of \( q_{l} / q_{0} \) and \( \nu_{\text{ph}} / \omega_{0} \).

We find that the ratio reaches values \( \geq 10\% \) for \( \nu_{\text{ph}} \geq 0.4\omega_{0} \) and \( l \) sufficiently small (\( q_{l} / q_{0} \approx 0.01 \)). The enhancement of \( \Delta \lambda / \lambda_{0} \) when decreasing the crystal thickness \( l \) can be understood by realizing that the function \( \Delta \lambda / \lambda_{0} \) entering eq 7 scales as \( \sim 1/(\nu_{\text{ph}} / \omega_{0}) \), as shown in the Supporting Information. This stems from the fact that the dressing of 3D phonons by 2D evanescent waves decaying exponentially at each interface increases when decreasing the crystal thickness. However, when the crystal thickness becomes too small (e.g., when \( K_{F} \ll 1 \)), the description of the matter excitations by 3D phonons becomes less accurate as the typical photonic and electronic wave vectors is reduced. This can occur in materials with larger phonon frequency and/ or lower electron density. In the latter case, however, decreasing \( K_{F} \) requires considering larger \( l \) for the 3D description of the matter fields to be valid, which in turn leads to a reduction of \( \Delta \lambda / \lambda_{0} \).

For instance, bilayer graphene with \( l \approx 0.4\text{nm} \) \(^{65}\) exhibits an infrared-active phonon mode at \( \hbar \omega_{q} = 0.2 \text{eV} \) and has been recently shown to feature superconductivity at low carrier densities \( \approx 2 \times 10^{12} \text{cm}^{-2} \) when the two sheets of graphene are twisted relative to each other by a small angle. \(^{52}\) In this regime, we find that \( \nu_{\text{ph}} \approx 0.25 \omega_{0} \approx 7 \times 10^{-4}K_{0} \approx 1.6 \times 10^{3}q_{0} \) and the large phonon–phonon coupling strengths \( \nu_{\text{ph}} \approx 0.25\omega_{0} \) \(^{42}\) allow reaching the ultrastrong coupling regime. Using these parameters, we find that the contribution of surface plasmon–phonon polaritons to the electron–phonon scattering is expected to reach a very large value \( \Delta \lambda / \lambda_{0} \approx 2.7 \). However, the

Figure 3. (a) Function \( \varphi_{q\eta} \) versus \( q / q_{0} \) for \( \nu_{\text{ph}} / \omega_{0} = 0.5, q_{l} / q_{0} = 0.01, \) and \( \omega_{l} = 1.5\omega_{0} \) corresponding to the red solid and dashed lines in Figure 2b. The contributions of symmetric (\( \sigma = + \)) and antisymmetric (\( \sigma = - \)) modes are depicted as dashed and solid lines, respectively. (b) Relative enhancement of the electron–phonon coupling parameter \( \Delta \lambda / \lambda_{0} \) given by eq 7 versus \( q / q_{0} \) and \( \nu_{\text{ph}} / \omega_{0} \) for \( \omega_{l} = 1.5\omega_{0} \) and \( K_{0} = 10^{3}q_{0} \).
small thickness of bilayer graphene such that $K_d l \sim 1$ in this weakly doped regime implies that quantum confinement effects become important. Furthermore, the failure of the 3D model assuming $\omega_{pl} \to \text{const}$ as $q \to 0$ can be seen in the dispersion of the optical plasmon mode in bilayer graphene,\textsuperscript{88} which is known to be $\omega_{pl} \sim \sqrt{q}$ as $q \to 0$.

\section*{CONCLUSION}

In summary, we have carried out a nonperturbative quantum theory of intrinsic, lossless plasmon–phonon polaritons valid for arbitrary large coupling strengths and discussed the different regimes of interest obtained by tuning the crystal thickness and the phonon–plasmon coupling strength. This theory allows characterizing the hybridization between plasmons and phonons in the crystal, which cannot lead solely to a modification of the electron–phonon scattering at the level of the RPA. Considering the coupling of these hybrid plasmon–phonon modes to photons, we have found that in the regime where both the electronic and ionic plasma frequencies become comparable to the phonon frequency, a dressed low-energy phonon mode with finite plasmon weight arises. In the case of quasi-2D crystals, the in-plane wave vector of this dressed phonon can reach very large values comparable to the Fermi wave vector, which is shown to lead to an enhancement of the electron–phonon scattering. It is an interesting prospect to investigate whether this effect could modify superconductivity in certain molecular crystals. While our model specifically addresses the case of metallic crystals with large ionic charges supporting far/mid-infrared phonons,\textsuperscript{22,85,94,95} it can be directly generalized to describe other types of excitations such as excitons and extended to other geometries. Further useful extensions include the presence of quantum confinement in 2D materials and dissipation. In addition to the intrinsic phonon linewidth, the main source of dissipation is the damping of plasmons with large wave vectors due to the electron–hole continuum (electronic dark modes).\textsuperscript{95} However, since the dressed phonons feature only a $\sim25\%$ plasmon admixture at large wave vectors, this effect is not expected to dramatically affect our results.
